Toward Dynamical Sensor Management for Reactive Wall-following

Avik De and Daniel E. Koditschek

Abstract—We propose a new paradigm for reactive wall-following by a planar robot taking the form of an actively steered sensor model that augments the robot’s motion dynamics. We postulate a foveated sensor capable of delivering third-order infinitesimal (range, tangent, and curvature) data at a point along a wall (modeled as an unknown smooth plane curve) specified by the angle of the ray from the robot’s body that first intersects it. We develop feedback policies for the coupled (point or unicycle) sensorimotor system that drive the sensor’s foveal angle as a function of the instantaneous infinitesimal data, in accord with the trade-off between a desired standoff and progress-rate as the wall’s curvature varies unpredictably in the manner of an unmodeled noise signal. We prove that in any neighborhood within which the third-order infinitesimal data accurately predicts the local “shape” of the wall, neither robot will ever hit it. We empirically demonstrate with comparative physical studies that the new active sensor management strategy yields superior average tracking performance and avoids catastrophic collisions or wall losses relative to the passive sensor variant.

I. INTRODUCTION

The ability to follow the boundary of obstacles in the environment gives a robot the freedom to navigate in a higher dimensional ambient space while keeping the motion control problem at the dimensionality of the boundary itself. There is an extensive literature on “bug”-style algorithms with various sensory enhancements and optimizations which provide guarantees on achieving specific navigation [1], mapping or pursuit-evasion [2] goals with sparse sensory and locomotory capabilities.

In this paper we focus on a kinematic planar robot equipped with an actively steerable infinitesimal sensor. The motivation behind our sensor model is that it is closely related to low-bandwidth sensors such as biological or bio-inspired active antennae/whiskers which sense distance [3], [4], tangent [5], [6] or texture [7], as well as to foveating high-bandwidth sensors such as a laser range scanner or a vision system [8] with shape-from-shading [9] or other attention-localizing [10] capabilities. The active steering ability brings an additional degree of freedom to be controlled. While the classical sensor management literature [11], [12], [13], [14], [15] focuses on optimal (with respect to estimation error or information theoretic considerations) sensor placement, we seek a real-time control strategy for the coupled sensorimotor system (which is assumed to have first-order dynamics, and respecting which the coupling must be specifically prescribed) for successful wall-following.

A. Brief Survey of Prior Literature

The past literature on wall-following robots is vast, however we can immediately distinguish this work from potential-field approaches [17], [18], which need a priori knowledge about the environment, as well as from approaches based on mapping [19], [20], which require more sophisticated sensors than assumed here and need relatively high computational power and memory. We want to restrict attention to the so-called “reactive” or “feedback” [21] paradigm of robot control, where the task is specified as a dynamical relation instead of a prescribed plan. Methods of this genealogy present desirable traits such as faster response time in the presence of disturbances and reduced computational cost, thereby reducing the complexity of the task while expressing a degree of robustness to unstructured environments due to the minimality of its model.

Even among reactive wall-following methods, there is a large literature [22], [23] on methods which successfully prove internal stability with smooth controllers in restrictive environments, with an added layer of discrete switching to circumvent an enumerated set of environmental obstacles. We argue that it is very difficult to make concrete conclusions about the stability or performance of the resulting hybrid system in the presence of unmodeled external perturbations. Our approach instead assumes a very myopic sensor with a...
correspondingly minimal environment model\(^3\); this simplicity admits a proof of successful wall-following by the robot in an unknown environment.

**B. Organization and Contributions of the Paper**

The central contributions of this paper are: (a) introduction of a novel active sensing model to the established problem domain resulting in an explicit sensor feedback control law (6) that is empirically shown to dramatically improve performance over a passive sensor implementation (robot experiments are reported in Section IV-A), (b) novel task specification relative to a continuum goal-set as a point-set in a *controlled* moving frame (see Section II), and (c) convergence and tracking guarantees in the (infinitesimal) moving frame (presented as Propositions 1, 2 and 3 in Section II) as well local\(^4\) guarantees of wall avoidance in Propositions 5 and 7 in Section III.

The intuition that a reactive wall-following robot in environments with corners could benefit from a positive (negative) look-ahead at concave (convex) corners motivates the need for a real-time active sensor. In some motivational prior work with an infinitesimal passive sensor for rapid wall-following\([25]\), the authors proved internal stability of the system and had a basis of attraction large enough to reject small external perturbations (corners), but it was necessary to resort to a switching control scheme to handle large deviations from equilibrium. We posit that our proposed active sensing strategy could be directly applied to eliminate the need for any heuristic switching.

While our “local” analysis is still myopic, we are able to provide conditions directly related to the robot state and curvature-like perturbation terms which can provide almost-global guarantees against failure, and which are not considered in typical controller stability analyses\([26], [27]\) in the prior literature from the best of our reading.

Absent an explicit model of the environment we perform the analysis in a moving local frame (a method introduced by Justh et. al.\([28]\)). Using this method, the task-induced symmetry\([29]\) presents itself as a nonzero “drift” term in our dynamical system, so that our goal manifold in world coordinates is just a point in the local frame—a fact that simplifies the analysis greatly. Further, our proposed unicycle controller of Section II-B demonstrates the advantages of a smooth controller that is allowed to set the speed as well as the turning rate. We hypothesize that a large body of existing unicycle control literature that assumes that the system has fixed forward speed\([24], [26]\) could benefit from this insight.

**II. INFINITESIMAL CONTROLLER**

Model the wall as a simple smooth plane curve of bounded curvature which has the explicit form \(b: \mathbb{R}_+ \to \gamma \subset \mathbb{R}^2\). Let \(Db\) denote the map to the tangent vector and \(\kappa\) the map to the signed curvature at a point on the curve. We don’t require that the curve be unit-speed parameterized, but define \(Db^\nu\) as the unit tangent, and \(\bar{\kappa} = |\kappa| / |Db|\) the normalized curvature. Define \(|\bar{\kappa}|_{\text{max}}\) as the maximum value attained by \(|\bar{\kappa}|\) function.

We assume without loss of generality that the goal is to traverse the curve along the direction \(Db\) while staying on the same side as the normal \(JDb\) (where \(J = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}\)), and to attempt to maintain a rate of progress \(\rho := \|Db\| / \bar{\kappa} \approx 1\).

Additionally, assume that if the robot position is \(p \in \mathbb{R}^2\), and \(b(\sigma)\) is the sensed point on the curve (implicitly assumed to be within some sensing range limit), then the infinitesimal sensor measures \(\|p - b(\sigma)\|\), \(Db(\sigma)\) and \(\bar{\kappa}(\sigma)\).

**A. Point Robot**

The unitary matrix \(E^T = (Db^\nu, J Db^\nu)\) can be used to change coordinates to and from the local tangent-normal frame, \(q = E(p - b(\sigma))\). Additionally, imagine that the point robot has a preferred “direction” oriented along \(Db\) (even though it has no motion constraints as the unicycle does), and note that \(\varphi = \angle q\) is the pointing angle of the sensor. In more intuitively illuminating terms, \(q_2\) is the wall standoff, and \(-q_1\) is the look-ahead distance. See Figure 2 for an illustration of the model.

Let both the robot and its sensor be kinematically driven, \(\dot{p} = E^T \bar{u}, \quad \varphi = v\), (1) where we define \(\bar{u} = (\bar{u}_1, \bar{u}_\perp)\) in the local frame for convenience. Some trigonometry yields

\[
\rho = \bar{u}_1 + \frac{\|v\|^2}{q_2} v. \tag{2}
\]

For convenience, we will substitute \(\rho \) for \(v\) in the system equations (1). (As long as \(q_2 > 0\) does not cross 0—a condition which is ensured in steady-state by the proof of Proposition 1—we can do this freely.) We examine the consequences of not having control of \(v\) (passive sensor) in Proposition 1.

Using the Frenet-Serret formulae\([30]\), \(\dot{E} = -\dot{\sigma} \kappa J E = -\rho \kappa J E\), and using (2), we get the simple local kinematics

\[
\dot{q} = \bar{u} + \rho \bar{\kappa} J \bar{E}, \tag{3}
\]
where we define \( n := -\epsilon_1 - \bar{\kappa} J_\theta \), an unmodeled “noise” vector which includes environmental disturbances through \( \bar{\kappa} \), and a constant drift because of the movement of the frame.

Define \( \dot{q}_2 := q_2 - (\delta^* + \frac{\bar{\kappa}_1 q_1^2}{2}) \) as the curvature-corrected tracking error, where our nominal standoff is \( \delta^* \).

**Proposition 1** (Point robot convergence). With active sensing, we can assure (a) \( \rho = 1 \) (desired rate of progress), (b) \( q_2 \to 1 \), and (c) \( q_1 \to 0 \), whereas with passive sensing we can only guarantee (a) and (b).

**Proof.** Suppose we want to minimize the cost

\[
\nu(q) = \frac{1}{2} q_1^2 + \frac{k}{2} q_2^2.
\]

We can simply set

\[
\ddot{u} = -D\nu(q) - \rho n
\]

\[
v = \frac{\dot{q}_2}{\|\dot{q}_2\|} \rho_{\text{desired}} - \ddot{u}
\]

to get the closed loop behavior

\[
\dot{q} = -D\nu(q), \quad \rho = \rho_{\text{desired}},
\]

which ensures \( \dot{\nu} = D\nu \dot{q} = -\|D\nu\|^2 \leq 0 \). In effect, we are using our three control inputs, \( u, \ddot{u}, v \), to control our three degrees of freedom \( q_1, q_2, \rho \). Section III-A includes a less myopic analysis of this controller.

Without active sensing, in (1) we lose the ability to control \( \rho \) through \( v \), in fact (2) reduces to \( \ddot{u} = \rho \). This turns (3) into

\[
\dot{q} = \begin{bmatrix} 0 \\ \ddot{u} \end{bmatrix} - \bar{\kappa} J_\theta q,
\]

showing that \( q_1 \) is uncontrollable. Large \( q_1 \) results in a detriment to the safety guarantees we can provide under this control by directly jeopardizing the pre-conditions of our proof of local wall-avoidance in Proposition 5.

\[ \Box \]

**B. Unicycle Robot**

The point robot design (illustrative simulations in Figs. 3 and 4) extends quite naturally to the unicycle (our horizontal plane model for a quasi-static RHex gait [16]). Define the matrix-valued function \( B : \text{SE}(2) \to \mathbb{R}^{1 \times 2} \) as

\[
B(x, y, \theta) = \begin{bmatrix} \cos \theta & 0 \\ \sin \theta & 0 \\ 0 & 1 \end{bmatrix}.
\]

We can model the kinematic unicycle with inputs \( u_1 \) (forward speed), \( u_2 \) (steering rate) and world frame coordinates \( (p, \theta) \in \text{SE}(2) \), as \( \dot{(p, \theta)} = B(p, \theta) u \).

Let \( r \in \text{SE}(2) \) be the local frame representation, and \( w = \Pi \nu \) be the projection onto the first two elements. We can follow the same general steps of Section II-A to get the moving-frame system dynamics

\[
\dot{r} = B(r) u + \rho n, \quad \dot{\phi} = v,
\]

where \( n \) is the same as before, and \( \phi \) is the angle of the pointing direction of the sensor relative to the axis of the unicycle, ie. \( \phi = \tan^{-1}(-E^T w) - \theta \). Similar trigonometry to (2) reveals that

\[
\rho = \begin{bmatrix} \cos r_3, \|w_2^2\|^2 \\ \|w_3^2\| \end{bmatrix} u + \frac{\|w_2^2\|}{w_2} v.
\]

As before, we find it easier to treat \((u, \rho)\) as our inputs, where \( v \) is held hostage by the linear constraint equation (10).

Assume that we would like to minimize the cost function \( \eta : \text{SE}(2) \to \mathbb{R}_+ \),

\[
\eta = k_\alpha (1 - \cos \alpha) + \frac{r_1^2}{2} + \frac{k}{2} r_2^2,
\]

where \( r_2 = r_2 - (\bar{\kappa} + \frac{\bar{\kappa}_1 q_1^2}{2}) \), \( r_3 = \tan^{-1}(-k r_2) \), \( \alpha = r_3 - r_3 \). The latter two summands are exactly the same as the in (4), and the first term serves the intuitive purpose of steering the unicycle in the direction counter to the offset error, \( \bar{\kappa} \).

Define \( B(p, \theta)^\times = (-\sin r_3, \cos r_3, 0) \), and note that the non-holonomic motion constraint intuitively results in the system doing a poor job of following the gradient field in the \( B^\times \) direction. The effect is more explicit if we change coordinates using the completion of the columns of \( B \). Let
P := [B, B^\infty], \Delta \eta = P[\xi]; \text{ then } \lambda = \zeta n^T B^\infty \text{ is the hard-to-cancel component of the gradient in the } B^\infty \text{ direction.}

Let \mu > 0 be a constant design parameter used to stipulate a “tube” around the \(B^\infty\)-axis, \(\mathcal{T}_\mu = \{ r : ||z||^2 \leq \mu, \lambda > 0 \}\), and let \(\mathcal{B}_\mu = \{ r \in \mathcal{T}_\mu : \zeta \neq 0 \}\). Geometrically, \(\mathcal{B}_\mu\) comprises the configurations such that \(-\Delta \eta\) points almost perpendicular to the unicycle’s forward axis.

We choose the controller
\[
\hat{v} = B^T (-\Delta \eta(r) - \rho n),
\]
where \(n = -e_1 - \hat{r}Jw\). This results in the closed loop dynamics
\[
\dot{r} = -Bz + \rho(n^T B^\infty)B^\infty, \quad \dot{\eta} = -||z||^2 + \rho \lambda.
\]

The unicycle does not offer sufficient control authority to simply “cancel out” the noise to get asymptotic stability in the presence of disturbances as was done for the point robot. However, we make the following claims:

**Lemma 2.** Outside the tube \(\mathcal{T}_\mu\), we are guaranteed to be reducing the cost: \(\dot{\eta} |_{r \notin \mathcal{T}_\mu} \leq 0\).

**Proof.** Notice in (15) that even though \(\dot{\eta}\) is contaminated by \(\eta\) is a noise term, we can control its magnitude with \(\rho\). We assume that the safety / stability criteria in \(\eta\) are more important than constant rate of progress \((\rho = 1)\), and so we use the definition (13), which has the property that \(\rho \approx 1\) when \(\lambda \leq 0\) and \(0 \leq \rho \leq \frac{\mu}{\lambda}\) when \(\lambda > 0\).\(^5\) So \(\dot{\eta} |_{r \notin \mathcal{T}_\mu} \leq -\mu + \mu = 0\). \(\Box\)

The only problem we have to guard against is getting stuck in \(\mathcal{B}_\mu\). To that end, we present below a “conservative” analysis that guarantees this. In simulation or experiment, we use more aggressive parameter values, but do not empirically observe any attractors in \(\mathcal{B}_\mu\).

**Proposition 3** (Conservative unicycle robot convergence). If \(\mu \approx 0\), the system is driven to \(\eta = 0\).

**Proof.** With this assumption, \(\rho > 0\) but \(z \approx 0\) in terms of contribution to (14), leading to the simplification \(\alpha \approx 0\).

The system dynamics restricted to \(\mathcal{B}_\mu\)
\[
\dot{\nu} |_{\mathcal{B}_\mu} = \frac{\rho \lambda}{\zeta} B^\infty,
\] where we are allowed to divide by \(\zeta\) because of the definition of \(\mathcal{B}_\mu\). Still restricting everything to \(\mathcal{B}_\mu\), some tedious multi-variable calculus shows that \(D(B^T \Delta \eta) \cdot B^\infty = (s, k_2) \neq 0\). Using this, we get
\[
\dot{\nu} |_{\mathcal{B}_\mu} = Dz |_{\mathcal{B}_\mu} \cdot \dot{\nu} |_{\mathcal{B}_\mu} = \frac{\rho \lambda}{\zeta} D(B^T \Delta \eta) \cdot B^\infty |_{\mathcal{B}_\mu} \neq 0,
\] which means that we are forced to exit \(\mathcal{B}_\mu\). We can conclude that the system is driven to \(\eta = 0\), via a trajectory that enters \(\mathcal{T}_\mu\) with \(\zeta = 0\). \(\Box\)

**III. Local Wall-avoidance Guarantees**

We claim that our proposed controllers guard against wall penetration in a region (hereafter called a “local” neighborhood of much larger size than the robot’s infinitesimal field of perception. We invoke a global implicit function representation of the curve (unknown to the robot) and use it to prove that the controllers of Section II prevent us penetrating the wall under explicit conditions.

**Proposition 4** (Wall implicit function). There exists a real-valued function \(\beta\) globally defined in a neighborhood of the curve such that
1. \(\beta \circ b \equiv 0\); it is positive on the side containing the outward normal and negative on the other side,
2. \(D\beta |_p = n(p)\), where \(p \in Y\) and \(n(p)\) is the unit outward normal to \(Y\) at \(p\), and
3. \(E \frac{\partial^2 \beta}{\partial n_p} = E^T = \begin{bmatrix} -\kappa(p) & 0 \end{bmatrix}\), where \(E\) is the change of basis to local coordinates at \(p\) (as in Section II-A).

**Proof.** Let \(T_\perp(Y)\) be the normal bundle of \(Y\), and \(N_\sigma(Y)\) be an \(\varepsilon\)-neighborhood of \(Y\) where the Tubular Neighborhood Theorem [31] holds. We conclude that there is a map \(T_\perp(Y) \rightarrow N_\sigma(Y)\) that sends \((p, \varepsilon n(p)) \rightarrow (p + \varepsilon n(p))\) for all \(\varepsilon < \varepsilon\) and \(\varepsilon\) small enough.

Further, since we are on the plane and normals are oriented, we assert that there is a diffeomorphism between \((p, \varepsilon n(p)) \in T_\perp(Y)\) and \((p, \lambda) \in Y \times (-\varepsilon, \varepsilon)\), letting us identify \((p, \lambda) \leftrightarrow (p, \lambda n(p))\).

Composing this last map with the one from the Tubular Neighborhood Theorem, we get the diffeomorphism \(f(p, \lambda) = (p + \lambda n(p))\). Let us define
\[
\beta = \pi_2 \circ f^{-1},
\] where \(\pi_2\) is the projection to the second element. Now we prove each of the subparts of the Proposition:

1. Observe that \(f(p, \lambda)\) for \(\lambda > 0\) lies in the same direction as the outward normal.
2. Taking a time derivative of the equation \(\beta \circ b = 0\) shows that \(D\beta |_{b(\sigma)} \cdot Db(\sigma) = 0\), so \(D\beta |_p\) is parallel to \(n(p)\). To check that it is of unit magnitude,
\[
D\beta |_p \cdot n(p) = \lim_{\lambda \rightarrow 0} \frac{\beta(p + \lambda n(p)) - \beta(p)}{\lambda} = 1
\]
3. Note that the hessian is symmetric, and we can find the (1,1) and (1,2) elements by taking derivatives of \(D\beta : Dbu = 0\) and \(D\beta : (JDb)^2 = 1\). For the (2,2) element, we will do a Taylor expansion of \(\beta\),
\[
\lambda = \beta(p + \lambda m) = \beta(p) + \lambda DB |_p + \frac{\lambda^2}{2} m^T D^2 \beta |_p m + o(\lambda^2)
\]
\[
\Rightarrow 0 = \lim_{\lambda \rightarrow 0} \frac{\lambda^2 m^T D^2 \beta |_p m}{\lambda^2} = \frac{\lambda^2}{2} m^T D^2 \beta |_p m + o(\lambda^2)
\]
and we can conclude that in the direction normal to the curve, \(m^T \Delta^2 \beta |_p m = 0\). \(\Box\)

Assume the robot is looking at a point \(b(\sigma) \in Y\). We will use a first-order Taylor expansion of \(D\beta\) for the analysis, and
so we need \(|p - b(\sigma)||\) to be small. Based on the properties of the curve, fix \(\varepsilon_r\) such that \([y \cap N_{\varepsilon_r}(b(\sigma))]\) is approximated well by the Taylor expansion.

A. Point Robot

**Proposition 5** (Point robot local safety condition). If \(2k\delta^* > \varepsilon_r\), then under the flow (7), we have
\[
\dot{\beta}|_{y \cap N_{\varepsilon_r}(b(\sigma))} > 0,
\]
i.e. the robot gets repelled from the wall into the safe region.

**Proof.** The Taylor expansion at \(p \in [y \cap N_{\varepsilon_r}(b(\sigma))]\) is
\[
\dot{\beta}{|}_p = D\beta{p} \cdot \dot{p} \approx q^T E \left( D\beta{b(\sigma)} + D^2\beta{b(\sigma)}E^T q \right) = q^T (\varepsilon_2 - [\frac{\varepsilon}{2} 0]) q = q^T [-\varepsilon q_1].
\]

Define \(y := [-\varepsilon q_1]\). Note that \(D\nu = q_1 e_1 + k_\delta q_2 y\). Using (5), (4), and the fact that \(q_2 = \frac{\varepsilon}{2} q^T\) on \(\beta^{-1}(0)\),
\[
\dot{\beta}{|}_p = k\delta^* ||y||^2 + \kappa q_1^2.
\]
Using the fact that \(\max_{r \geq 0} \frac{-\varepsilon q_1}{1 + \kappa q_1} = \frac{q_1}{2}\),
\[
\left|\frac{-\varepsilon q_1}{1 + \kappa q_1}\right| = \frac{|q_1|}{1 + \kappa q_1} \leq \frac{|q_1|}{2}.
\]
Going back to (18), we get
\[
\dot{\beta}{|}_p \geq ||y||^2 (k\delta^* - \frac{|q_1|}{2}) \geq 0,
\]
by the given condition as long as we are in \(N_{\varepsilon_r}(b(\sigma))\). The condition of being in the \(\varepsilon_r\)-ball is automatically enforced by the asymptotic stability guarantee of (5).

This result together with the claims in Proposition 1 shows that the active sensing capability is crucial in giving safety and performance guarantees. \(\square\)

B. Unicycle Robot

Unlike the point robot, it is necessary for the unicycle to allow a buffer region or “collar,” \(\mathcal{C} \approx [y \times (0, \varepsilon_u)]\), of width \(0 < \varepsilon_u \ll \delta^*\) in which the controller has time to act. Define \(\partial \mathcal{C} := \text{Im}(b + \varepsilon_u (n \circ b))\), the curve which is the \(\varepsilon_u\)-extrusion of the wall. We show that if the robot starts from an arbitrary configuration on \(\partial \mathcal{C}\), then the control (12) prevents a collision.

If the local frame coordinates of the robot are \(r \in \text{SE}(2) \cap (N_{\varepsilon_r}(0) \times S^1)\), define \(y := [-\varepsilon r_1]\) and \(\chi := \frac{\varepsilon^2 r_2}{2 ||y||}\). The following Lemma establishes some technical results necessary for our proof of wall-avoidance in Proposition 7.

**Lemma 6.** On the boundary of the collar, \(\partial \mathcal{C}\), the closed loop system (14) exhibits
1) \(\dot{\beta}|_{\partial \mathcal{C}} \geq -(1 + \chi) ||y||^2\), and
2) \(\beta < 0 \implies \dot{\beta} \geq 2k\delta^* ||y||^2 (k_\alpha - |\kappa|_{\max})\).

**Proof.** On \(\partial \mathcal{C}\), \(r_2 = \frac{\kappa^2}{2} + \varepsilon_w\). Assume that \(k\) is large enough that \(k\delta^* \gg \varepsilon_w\). We get the simplifications (a) \(-D\eta \approx k\delta^* y\), and (b) \(n = Jy + \frac{k\delta^*}{2} e_1 = Jy + \chi ||y|| e_1\), where .

1) Just like the particle computation above,
\[
\dot{\beta} = y^T \dot{w} \geq ||y||^2 (k\delta^* (c^T_y y^u)^2 - \rho - \rho \chi).
\]
The lower bound to this (in the Lemma statement) is attained when \(c^T_y y^u = 0\) and \(\rho = 1\).

2) If \(\beta < 0\), then \(|c^T_y y^u|\) is small; let \(c^T_y y^u = \xi\) where \(k\delta^* \xi \geq 1 + \chi\). Additionally, without loss of generality choose the sign \((y^u)^T J e_u = 1\). Then
\[
\dot{\beta} = ||y||^2 (k\delta^* \xi^2 + \rho \chi + \rho \chi c^T e_v e_2). \tag{19}
\]
Let \(R_0 = e^{\alpha \cdot J}\) \(SO(2)\), and then \(e_{\rho} = R_0 e_e\). Taking a derivative, and noting that the closed-loop system (14) sets \(\alpha = k_\alpha \sin \alpha \lambda\) to \(e_{\rho} = k_\alpha \sin(\alpha) J e_{\rho},\) and \(\xi = (k_\alpha \sin(\alpha) - \rho \kappa)\). Note that
\[
\sin \alpha = c^T_2 R_0 e_1 = c^T_2 e_1 = c^T_y J^T J e_1 = (y^u)^T J e_{\rho} = 1 = (k_\alpha \sin(\alpha) - \rho \kappa).
\]
which means \(c^T_2 e_{\rho} \approx 0\). Lastly,
\[
||y||^2 = 2 ||y|| ||y^u|| = 2 ||y||^2 (-\rho \kappa (y^u)^T J) = 0.
\]
Using these in (19), we get
\[
\dot{\beta} = ||y||^2 (2k\delta^* \xi + \rho) \xi \geq 2k\delta^* ||y||^2 (k_\alpha - |\kappa|_{\max}).\tag{\square}
\]

In the following Proposition, we use an infinitesimal condition, \(w \in N_{\varepsilon_r}(0)\)—which is under the jurisdiction of the infinitesimal controller’s tracking prowess—to give a local guarantee of success.

**Proposition 7** (Unicycle robot local safety condition). If the robot with local coordinates \(r\) such that \(w(0) \in N_{\varepsilon_r}(0) \cap \partial \mathcal{C}\) uses a controller where the controller gains are such that
\[
k_\alpha \geq |\kappa|_{\max} + \frac{1 + 2|\kappa|_{\max} \varepsilon_u^2}{(1 + |\kappa|_{\max}^2) \varepsilon_u^2}, \tag{20}
\]
then
1) the maximal “incursion time” that the robot can spend inside \(\mathcal{C}\) approaching the wall (with \(\beta < 0\)) is
\[
t_u \leq \frac{2k\delta^* (|k_\alpha|_{\max} - \varepsilon_u^2)}{1 + \chi (|\kappa|_{\max}^2)} \tag{\text{and}}
\]
2) the robot does not reach the wall in this incursion period, i.e. \(\min_{t \leq t_u} \beta(t) = \beta(t_u) > 0\).

**Proof.** Assuming we start at time \(t = 0\) at a distance \(\varepsilon_w\) from the wall, the latest time \(t_u\) by which \(\beta(t)\) crosses 0 is given by
\[
0 = \dot{\beta}(0) + \int_0^{t_u} \dot{\beta} \\
\geq t_u (2k\delta^* ||y||^2 (k_\alpha - |\kappa|_{\max})) - (1 + \chi) ||y||^2,
\]
chosen aggressively (e.g. $\mu$ performance with ground truth [32] data in Fig. 6. We present the tracking of typical indoor environments, right-angle corners (robot A. Comparing Active to Passive Sensing

parameters

laser scanner as in Fig. 5, and choose appropriate controller

a sufficient condition for which is exactly (20).

$\beta(t_i) \geq 0$, we need

$$\beta(t_i) = \varepsilon_w + \int_0^{t_i} \dot{\beta} \geq \varepsilon_w - (1 + \chi)\|y\|^2 t_i,$$

a sufficient condition for which is exactly (20).

As a consequence of this Proposition, we can be assured that even if the robot approaches the wall at an arbitrarily bad configuration, the control action manages to steer it away from the wall and avoid failure within the $\varepsilon_w$ collar.

IV. ROBOT EXPERIMENTS

We use the XRL platform [16] with a Hokuyo UBG-04LX-F01 laser scanner mounted rigidly, such that we scan on the horizontal plane in a $240^\circ$ arc in front of the robot.

We instantiate our modeled infinitesimal sensor from the laser scanner as in Fig. 5, and choose appropriate controller parameters$^6$ for all of the following experiments.

A. Comparing Active to Passive Sensing

We set up a test course with the basic building blocks of typical indoor environments, right-angle corners (robot moves from right to left in Fig. 1). We present the tracking performance with ground truth [32] data in Fig. 6.

and the first claim follows. The $N_{\varepsilon_w}(0)$ bound provides $\chi \leq 2|\dot{\varepsilon}_w|_{\text{max}} \varepsilon_r$ and $\|y\| \leq 1 + |\dot{\varepsilon}_w|_{\text{max}} \varepsilon_r^2$. Using our lower bound on $\beta$, we can check that to ensure $\beta(t_i) \geq 0$, we need

$$\bar{\beta} = \varepsilon_w + \int_0^{t_i} \dot{\beta} \geq \varepsilon_w - (1 + \chi)\|y\|^2 t_i,$$

the experiments validate our general intuition that for a reactive behavior, a constant-$\varphi$ strategy is easily defeated on at least some kind of corner or feature in the environment.

B. Application to Complex Real-world Environments

Even though our model world assumes bounded curvature, the perturbation rejection characteristics of our controller enables us to get good performance in unmodeled and relatively unstructured environments. Because of the lack of a portable ground-truth mechanism, the trajectories in figures in this subsection were generated by manual scan-matching, and are thus suggestive but not exact.

Fig. 7 shows the robot tracking the wall in an indoor hallway with sharp corners and clutter successfully. Note that the measured $\bar{\kappa}$ is what primarily affects tracking error.

Fig. 8 gives anecdotal evidence of some settings where the controller-sensor combination fails, as detailed in the caption.

V. CONCLUSIONS AND FUTURE WORK

We have developed a real-time method for feedback control of a coupled sensorimotor system for two planar kinematic systems. We have supplied some analytical guarantees of controller stability and convergence (Section II), and guarantees against failure (Propositions 5 and 7) as long as the robot stays near the sensed point (Section III).

We have implemented this controller on a RHex robot, and demonstrated (a) that it performs qualitatively better than an equivalent passive-sensor system (Section IV-A), and (b) good tracking capability in unmodeled real-world settings (Section IV-B). We envision that the wall-following capability can augment more complex behaviors, such as landing behavior in autonomous stair-climbing [33].

In this paper we restricted ourselves to a first-order model for robot and sensor, and a future extension to second-order systems seems natural. For the progress-rate goal, this would enable the construction of a point attractor around the landing behavior in autonomous stair-climbing [33].

The speed of the robot in our experiments was limited by invalidity of the unicycle model assumptions at high speeds, resulting in failure to execute the desired control (12). In

The experiments validate our general intuition that for a reactive behavior, a constant-$\varphi$ strategy is easily defeated on at least some kind of corner or feature in the environment.

$^6$ We use a range of 0.2 - 0.5 meters standoff and our parameter values are chosen aggressively (e.g. $\mu = 0.1$, or $\varepsilon_w$ chosen opportunistically to match the “bumpiness” of the wall) relative to the conservative “guaranteed” values in Propositions 3 and 7, albeit with no adverse empirical consequences.
the future we would like to adapt an LLS model [34] for our robot, which could be better suited to control of an even faster wall-following behavior.

ACKNOWLEDGMENTS

We thank Dan Guralnik for his insight and help with Proposition 4, and Karl Bayer for initial experimental evidence and programming infrastructure development.
